Use of carbon dioxide lasers in dentistry

case report

Treatment of oral leukoplakia with a 980 nm diode laser

case report

Facial swelling caused by infected teeth

The universe at your fingertips.

● LightWalker

The highest technology dental laser system

Supreme clinical results:

- TwinLight® Perio Treatments
- TwinLight® Endo Treatments
- No-sutures soft-tissue surgery
- Patient-friendly conservative dentistry
- Pre-sets for over 40 applications

Unmatched simplicity of use:

- Balanced and weightless OPTOflex® arm
- Nd:YAG handpiece detection system
- Quantum Square Pulse technology for fast minimally invasive treatments
- X-Runner™ - the first digitally controlled Er:YAG dental laser handpiece

Journey into a new dental experience with speed, precision and great results.

Prof. Dr Norbert Gutknecht

ISLD President and Scientific Chairman

Together towards a **bright** future

Dear friends and colleagues,

I believe that all of us dental laser users worldwide would love to see a bright future for laser dentistry. Your participation in our International Society for Laser Dentistry (ISLD), German association for laser dentistry (Deutsche Gesellschaft für Laserzahnheilkunde—DGL) and World Academy for Laser Education and Research in Dentistry (WALED) congresses, held from 6 to 8 June in Plovdiv in Bulgaria, was essential for strengthening not only the ISLD but also the participating national societies, which are constantly striving to enrich the knowledge of their members and to promote professional excellence in the use of dental lasers through research and education.

Plovdiv, the oldest city in Europe, has been designated the 2019 European Capital of Culture. It was, thus, only natural that the city, founded 4,000 years ago, had unanimously been selected as the venue for the 17th International Congress of the ISLD, the 28th annual meeting of the DGL and the 7th WALED Congress. Our Organising Chairman, Dr Georgi Tomov, his team and the entire Bulgarian Society for Laser Dentistry did a fantastic job

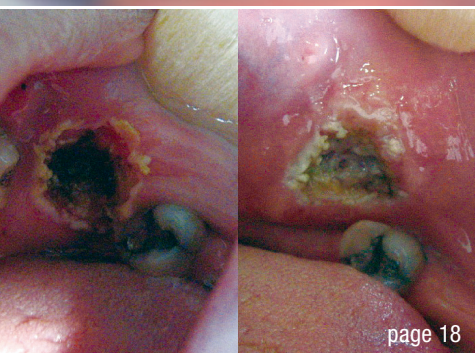

in hosting more than 250 laser enthusiasts from around the globe in their beautiful city.

I would like to express my deepest gratitude to everyone who attended our congress in Plovdiv and joined us for an outstanding event that brought technology and culture together to create an unforgettable experience.

I am already looking forward to our next World Congress, to be held from 1 to 3 October 2020 in Cairo in Egypt. Save the date and join us for yet another great celebration of laser art and science, helmed by the ISLD—the leading society worldwide for laser dentistry.

Yours

Use of carbon dioxide lasers in dentistry

Dr Kenneth Luk, Irene Shuping Zhao, China; Prof. Norbert Gutknecht, Germany & Prof. Chun Hung Chu, China

“Laser” is an acronym that stands for “light amplification by stimulated emission of radiation”.¹ The photons that make up a laser beam are coherent, amplified in phase (standing wave) and of a specific wavelength (monochromatic). Laser has been used in dentistry for over two decades.² Dental lasers are categorised according to their active medium and wavelengths. The currently available dental lasers are diode lasers (445, 635 and 810–980 nm), potassium titanyl phosphate lasers (532 nm, green), neodymium-doped yttrium aluminium garnet (Nd:YAG) la-

asers (1,064 nm), erbium lasers (2,780 and 2,940 nm) and carbon dioxide (CO₂) lasers (9,300 and 10,600 nm). Each laser wavelength has a specific thermal output and a particular tissue interaction.

Dental lasers of different wavelengths are used to perform different procedures. Blue lasers, diode lasers, Nd:YAG lasers and CO₂ lasers are primarily used in soft-tissue surgery to provide good coagulation.^{3–6} Because CO₂ laser energy is well absorbed by water, it is absorbed on the surface of the soft tissue. The visible lasers (445–660 nm) are absorbed within the first centimetre of the soft tissue because they are best absorbed by pigmented chromophores such as melanin and haemoglobin. Lasers with 810 to 1,064 nm wavelengths in the near-infrared spectrum can penetrate into the soft tissue by a few centimetres because they are comparatively less well absorbed by melanin and haemoglobin. Erbium lasers, operating in free-running pulse mode, are highest in water absorption, enabling their use for soft-tissue ablation, as well as for dental hard tissue and osseous preparation. The two erbium wavelengths commonly used in dentistry are erbium, chromium-doped yttrium, scandium, gallium and garnet (Er,Cr:YSGG) lasers (2,780 nm) and erbium-doped yttrium aluminium garnet (Er:YAG; 2,940 nm) lasers. Although erbium lasers can be used for soft-tissue procedures, bleeding control is less effective than with diode and CO₂ lasers, which offer better visualisation of the surgical site.⁶ A CO₂ laser is a useful and efficient gas laser for use in clinical dentistry. It is available in 10,600 nm on the market (Table 1).

CO₂ lasers are often used in soft-tissue surgery because their wavelengths are well absorbed by water, which makes up 70% of biological tissue. They penetrate less than a millimetre and can produce excellent coagulation, along with a very precise cut.^{7,8} The optical property of the wavelength in tissue is important to determine the use of lasers to perform dental hard-tissue preparation. Enamel and dentine are mainly composed of hydroxyapatite, which has a high absorption coefficient to the wavelengths of CO₂ lasers. Nevertheless, it takes time for a CO₂ laser to ablate dental hard tissue, which contains mainly hydroxyapatite, with a melting point over 1,600 °C.

Model	Manufacturer	Location

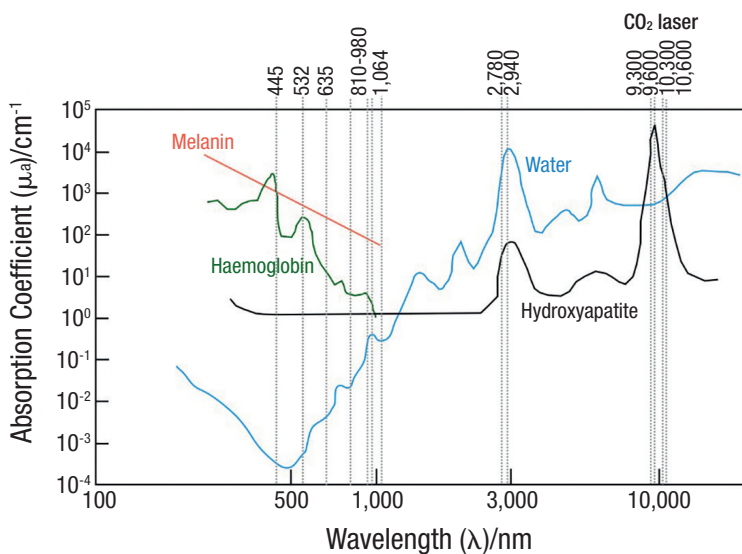

Fig. 1: Absorption spectra (log scale) of several biological materials and laser wavelengths (adapted from Zuerlein et al.¹⁵).

The time required results in carbonisation, melting and cracking of enamel.⁹⁻¹¹ The transversely excited atmospheric pressure (TEA) CO₂ laser was developed by energising a gas laser with a high-voltage electrical discharge in a gas mixture, generally above atmospheric pressure.¹² A pulsed low-energy CO₂ laser is available with very short pulse durations of a few microseconds with a high repetition rate (frequency) of over 1,000 Hz per second. These developments make CO₂ lasers suitable for dental hard-tissue preparation.¹³ In this paper, the production of CO₂ lasers and their technological advancement, optical properties, and parameters in relation to clinical applications in dentistry will be discussed.

Production of CO₂ lasers

The CO₂ laser was one of the earliest gas lasers to be developed, in 1964.¹⁴ It is one of the most useful and continuous-wave lasers currently available. The lasing medium is a gas discharge, and the three main filling gases within the discharge tube are CO₂, nitrogen (N₂) and helium (He). With electrical discharge, microwave or radio frequency, electron impact excites the vibrational motion of N₂ molecules. This marks the beginning of the population inversion, where molecules in the system are in their excited states. N₂ cannot lose this energy by photon emission because it is a homonuclear diatomic molecule. Excited vibrational levels are relatively long-lived and in a metastable state. The energy transfer that occurs owing to the collision between N₂ molecules and CO₂ molecules causes vibrational (resonant) excitation of CO₂ molecules, with sufficient efficiency to lead to the required population inversion of CO₂ for laser operation (collision of the second kind). The N₂ molecules are then returned to ground state.

The CO₂ molecules are still at a higher energy level after emission of photons. They return to ground state by colliding with cold He atoms. The resulting hot He atoms can be cooled by striking the bore (wall of the tube). The pressure in the tube must be low for adequate flow of photons. This limits the amount of CO₂ molecules in the tube, producing a low-power laser. The photons emitted owing to transition between energy levels have low energy and a longer wavelength than visible and near-infrared light because the energy levels of molecular vibration and rotation are similar.

Technological advancements of CO₂ lasers

More than one laser wavelength can be produced by a CO₂ gas laser. The wavelength depends on the isotope and resonator amplifying the wavelength desired. In dentistry, the 10,600 nm (¹²C¹⁶O₂ molecule) wavelength is the earliest and most commonly produced wavelength. A CO₂ laser is more efficient than other lasers because of its comparatively higher ratio of output power to pump power. Higher peak powers of CO₂ lasers can be achieved by slow flowing of the gas instead of using a sealed tube. Another method to achieve higher peak power is to increase the density of excited CO₂ molecules (i.e. the gas pressure). However, the voltage needed to achieve gas breakdown and couple energy into the upper laser levels also increases. The method to prevent production of a high voltage is to pulse the voltage transversely to the laser axis. Because electrical discharge can move transversely perpendicular to the laser axis, the electrons can travel at a substantially shorter distance and collide with more molecules.¹² The TEA CO₂ laser has such a design. The TEA CO₂ laser can achieve

Wavelength of CO₂ lasers (nm)

high peak power in short pulses (~2 μs) and at a high repetition rate. The 9,300 nm CO₂ laser was approved by the U.S. Food and Drug Administration (FDA) and introduced in 2010 for both hard- and soft-tissue surgery (Solea, Convergent Dental). The 9,300 nm wavelength is produced by using an isotope ¹²C¹⁸O₂ gas molecule instead of the normal ¹²C¹⁶O₂ molecule. Both ¹⁸O and ¹⁶O are naturally stable CO₂ molecules. Because ¹⁸O is heavier, with extra two neutrons, the frequency and energy level of molecular vibration are different from those of ¹⁶O.¹³

Optical properties and laser parameters

Clinical applications with CO₂ lasers rely on understanding of optical properties (how tissue acts on laser energy) and laser parameters (how laser energy acts on tissue). Different isotopes contained in the CO₂ molecule generate different output wavelengths of CO₂ lasers. A CO₂ laser generates a beam of infrared light with the wavelength bands primarily at 9,300; 9,600; 10,300 and 10,600 nm. The CO₂ wavelengths lie in the far-infrared electromagnetic spectrum. The main chromophores

are water and hydroxyapatite. Figure 1 shows the absorption spectra in log scale of common biological materials of common dental lasers. The absorption coefficients of all CO₂ wavelengths to water are very similar. The 10,600 nm CO₂ wavelength has an absorption coefficient to water of approximately 6.6 × 10² cm⁻¹. This gives an absorption or penetration depth (reciprocal of absorption coefficient) of 15 μm in water. Because soft tissue contains over 70% water, this makes CO₂ laser wavelengths suitable for soft-tissue surgery. The CO₂ wavelengths have a higher absorption coefficient to hydroxyapatite than to water. Among the four CO₂ laser wavelengths, 9,600 nm has the best absorption coefficient to hydroxyapatite, which is the main component of enamel and dentine. Table 2 provides a summary of the absorption coefficients and depth of 9,300; 9,600; 10,300 and 10,600 nm CO₂ laser wavelengths in enamel and dentine.¹⁶ The absorption depths in enamel and dentine of 9,300 and 9,600 nm wavelengths are shallower than for 10,300 and 10,600 nm wavelengths. Variations in laser parameters acting on enamel and dentine produce different thermal effects.

Early studies investigated the interaction of CO₂ wavelengths and laser parameters on surface temperature increase, surface melting, morphological surface changes and chemical changes on the enamel surface.¹⁸⁻²¹ These early studies showed how a combination of the fluence and pulse duration of CO₂ lasers acts on different enamel surface changes (Figs. 2-4). At 4-6 J/cm² and a 100 μs pulse, a temperature increase of 590-770 °C (Fig. 4) with 10,300 and 10,600 nm wavelengths is expected to reduce the carbonate, acid phosphate and protein content of enamel (Table 3). After shortening the pulse duration to 50 μs, the melting effect was observed with a 10,600 nm wavelength at 5 J/cm², suggesting a temperature increase of over 1,000 °C (Fig. 3). However, enamel ablation without carbonisation was reported with a pulse duration of between 10 and 20 μs at 30 J/cm².²² For 9,300 and 9,600 nm wavelengths with 4-6 J/cm² and a 100 μs pulse, the temperature increase (720-1,150 °C) is higher than for 10,300 and 10,600 nm wavelengths owing to the higher absorption coefficient. This rise in temperature correlated with the observed surface melting on enamel (Fig. 2).

Currently, the parameters for a 9,300 nm CO₂ laser (Solea) operate uniquely in dental hard-tissue ablation and differently from 10,600 nm CO₂ lasers in soft-tissue ablation. According to the manufacturer's specifications, the laser operates between 1 and 130 μs, with a maximum pulse energy of 42.5 mJ and 1,019 Hz at 130 μs. These parameters are not displayed on the control panel. The parameters were measured using a PowerMax-Pro 150F HD, 50 mW, 150 W fan-cooled sensor and LabMax-Pro SSIM Laser Power Meter (both Coherent). For adult hard-tissue mode, Figure 5 shows the pulses measured (from the authors' unpublished data). Fifty-three

pulses (30–106W) are delivered in 43µs, followed by a pulse pause of 13µs. The frequency is calculated as 950 pulses per second. The laser operates differently in soft-tissue mode. For example, at 0.75 mm spot size, the frequency is constant at 187Hz, while the peak power is 150W at 10% power. The peak power is 260W at 20–100% power (Fig. 6). Pulse duration increases from 16.5µs at 10% power to 133µs at 100% power (from the authors' unpublished data; Fig. 7).

Laser interactions with dental hard tissue and their clinical applications

Although many laboratory and clinical studies have been conducted with CO₂ lasers on dental hard tissue, only recently could these findings be clinically implemented because there is currently only one 9,300 nm CO₂ dental laser approved for hard-tissue application by the FDA. Laser interactions with dental hard tissue fall into three major categories, namely: (1) interaction with the mineral; (2) interaction with the protein and lipid; and (3) interaction with the water.²³ CO₂ lasers can be used in tooth ablation and caries prevention. For ablation, the fluence must be above the ablation threshold, the point above which sufficient energy has been added to the surface in a short enough period to cause expansion and/or vaporisation of the tissue. In the case of CO₂ lasers, absorption in both the mineral and water will occur with some melting and vaporisation of the mineral at around 1,000 °C and above, as well as heating and expansion of subsurface water. It has been reported that the use of a 9,300 nm CO₂ laser with a fluence of 9–42 J/cm² at a higher repetition rate (300Hz) can ablate enamel and dentine effectively.²⁴

The role of CO₂ lasers in dental caries prevention has been explored since the 1960s. For caries prevention purposes, it is likely that the most effective wavelengths are those that are most strongly absorbed by the mineral of dental hard tissue. The CO₂ laser wavelengths of 9,300; 9,600; 10,300 and 10,600 nm overlap with the

Fig. 4: Temperature rise of enamel after irradiation with carbon dioxide lasers. Irradiation parameters: single pulse of carbon dioxide wavelengths of 4–6 J/cm² and 8–10 J/cm² at 100 µs (data adapted from Fried et al. and Fowler & Kuroda^{20,21}).

strong phosphate absorption bands of the mineral. To prevent dental caries, the laser light must alter the composition or solubility of the dental substrate and the energy must be strongly absorbed and efficiently converted to heat without damage to the underlying or surrounding tissue.²⁵ Studies on the effects of CO₂ lasers have focused on increasing the resistance to caries by reducing the rate of subsurface enamel and dentine demineralisation.^{26,27} A greater depth of carbonate loss in enamel with a 10,600 nm CO₂ laser was observed compared with that with a 9,600 nm CO₂ laser.¹⁷ Featherstone and Frieda reported that using a pulsed 9,600 nm CO₂ laser produced an 84% inhibition of demineralisation in an intraoral cross-over study.²³ Furthermore, some studies have combined the effects of lasers with those of fluoride.^{28,29} In an *in vivo* study, Rechmann et al. showed that occlusal fissures irradiated with a 9,600 nm CO₂ laser followed by fluoride varnish application twice a year were more resistant to caries than fissures that did not undergo irradiation.³⁰ Another study using a 9,300 nm CO₂
